Abstract

Let $C$ be a non-empty finite set, and $\Gamma$ a subgroup of the symmetric group $S(C)$. Given a bijection $f : A \times C \to B \times C$, the problem of $\Gamma$-equivariant division is to find a quotient bijection $h : A \to B$ respecting whatever symmetries $f$ may have under the action of $S(A) \times S(B) \times \Gamma$. Say that $\Gamma$ is fully cancelling if this is possible for any $f$, and finitely cancelling if it is possible providing $A, B$ are finite. Feldman and Propp showed that a permutation group is finitely cancelling just if it has a globally fixed point. We show here that a permutation group is fully cancelling just if it is trivial. This sheds light on the fact that all known division algorithms that eschew the Axiom of Choice depend on fixing an ordering for the elements of $C$.

1 Introduction

Let $C$ be a non-empty finite set, and $\Gamma$ a subgroup of the symmetric group $S(C)$. Given a bijection $f : A \times C \to B \times C$, the problem of $\Gamma$-equivariant division is to find a quotient bijection $h : A \to B$ respecting whatever symmetries $f$ may have under the action of $S(A) \times S(B) \times \Gamma$.

Specifically, given

$$(\alpha, \beta, \gamma) \in S(A) \times S(B) \times \Gamma,$$

*The authors hereby waive all copyright and related or neighboring rights to this work, and dedicate it to the public domain. This applies worldwide.*

1
let
\[ f_{\alpha,\beta,\gamma} = (\alpha^{-1} \times \gamma^{-1}) \triangleleft f \triangleleft (\beta \times \gamma), \]
and
\[ h_{\alpha,\beta} = \alpha^{-1} \triangleleft h \triangleleft \beta, \]
where the symbol \( \triangleleft \), pronounced ‘then’, represents the composition of functions in the natural order, with first things first:
\[ (p \triangleleft q)(x) = q(p(x)). \]
We say that \( h \) is a \( \Gamma \)-equivariant quotient of \( f \) if whenever \( f_{\alpha,\beta,\gamma} = f \) we have \( h_{\alpha,\beta} = h \). \( \Gamma \) is fully cancelling if every bijection \( f : A \times C \to B \times C \) has a \( \Gamma \)-equivariant quotient, and finitely cancelling if this is true providing \( A, B \) are finite.

Feldman and Propp [3] looked at the finite case. They showed that the subgroup \( S(C, \star) \) fixing a designated basepoint \( \star \in C \) is finitely cancelling, but unless \( C \) is a singleton, the full group \( S(C) \) is not. Going further, they gave a beautiful proof that \( \Gamma \) is finitely cancelling just if it has a globally fixed point.

Here we are interested in the infinite case. The general problem of division is to produce from \( f : A \times C \to B \times C \) any quotient bijection \( h : A \to B \), equivariant or not. Known division methods that eschew the Axiom of Choice (cf. [1, 2, 5]) produce quotients that respect any symmetries under the action of \( S(A) \times S(B) \), so they are at least \( S_0(C) \)-equivariant, where \( S_0(C) \) is the trivial subgroup of \( S(C) \). But these methods depend on fixing an ordering of \( C \), suggesting that this is the most equivariance we can hope for. And indeed, we will show that \( \Gamma \) is fully cancelling just if it is the trivial subgroup \( S_0(C) \).

2 Finently cancelling

For starters, Feldman and Propp showed that if you specify a base point \( \star \in C \), the subgroup \( S(C, \star) \) of \( S(C) \) that fixes \( \star \) is finitely cancelling.

Here’s the argument. For \( c \in C \) define a map (not generally a bijection)
\[ f|_c : A \to B, \]
\[ f|_c(a) = f \triangleleft \pi_1(a, c), \]

2
where
\[ \pi_1((x, y)) = x. \]

Let
\[ p(a) = f|_*(a) = (f \lhd \pi_1)(a, \ast) \]

and
\[ q(b) = f^{-1}|_*(b) = (f^{-1} \lhd \pi_1)(b, \ast). \]

Because \( A \) is finite, the composition \( p \circ q \) has some cycles. Let \( X \subset A \) be the union of all these cycles. The restriction \( p|X \) is a partial bijection from \( A \) to \( B \). Subtract \( p|X \times \text{id}_C \) from \( f \) (cf. [11 2 3]) to get a bijection from \( (A - X) \times C \) to \( (B - p(X)) \times C \). Proceed by recursion to get a bijection \( \text{FP}(f, \ast) : A \to B \).

To sum up:

**Proposition 1** (Feldman-Propp). *If some \( \ast \in C \) is fixed by every \( g \in \Gamma \), \( \Gamma \) is finitely cancelling.*

We can collect the various bijection \( \text{FP}(f, c) \) for \( c \in C \) into a new bijection
\[
\bar{f} : A \times C \to B \times C,
\]
\[ \bar{f}((a, c)) = (\text{FP}(f, c)(a), c). \]

This new bijection \( \bar{f} \) satisfies
\[ \bar{f}((a, c)) = (\bar{f}|_c(a), c). \]

We will call any bijection that preserves the second coordinate in this way a parallel bijection.

By combining all the bijections \( \text{FP}(f, c) \) in this parallelization \( \bar{f} \), we obviate the need to choose a basepoint, so Proposition [1] implies (and follows from):

**Proposition 2.** *To a finite bijection \( f : A \times C \to B \times C \) we can associate in a fully equivariant manner a new bijection \( \bar{f} \) with
\[
\bar{f}((a, c)) = (f_c(a), c)
\]

where \( f_c : A \to B \) is a bijection for each \( c \in C \).*
In light of Proposition \[\text{2}\], \(\Gamma \subset S_C\) is finitely cancelling just if any finite parallel bijection has a \(\Gamma\)-equivariant quotient. Indeed, to any finite \(f\) we can associate its parallelization \(\bar{f}\); if \(\bar{f}\) has a \(\Gamma\)-equivariant quotient then so does \(f\); if it does not, then \(\Gamma\) is not cancelling.

This does not necessarily mean that in every finite division problem we can safely parallelize \(f\) as our first step. It could be that \(f\) has a \(\Gamma\)-equivariant quotient while its parallelization \(\bar{f}\) does not. (See [6.3])

Proposition \[\text{2}\] fails in the infinite case; this fact underlies the counterexamples we will produce there.

### 3 Not finitely cancelling

We begin with counterexamples in the finite case, all obtained using the method of Feldman and Propp.

The simplest case is \(C = \{a, b\}\). Take \(A = \{x, y\}\), \(B = \{1, 2\}\), and

\[
\begin{array}{c|cc}
  & x & y \\
\hline
  a & 1a & 2a \\
  b & 2b & 1b \\
(a, b)(1, 2)
\end{array}
\]

Here \(A \times C\) is the set of locations in a matrix with rows indexed by \(C\) and columns indexed by \(A\). An entry \(1a\) represents \((1, a) \in B \times C\), etc. The \((1, 2)(a, b)\) underneath indicates a symmetry of \(f\), obtained by taking \(\alpha\) to be the identity, \(\beta = (1, 2)\), and \(\gamma = (a, b)\). Performing these substitutions yields

\[
\begin{array}{c|cc}
  & x & y \\
\hline
  b & 2b & 1b \\
  a & 1a & 2a \\
\end{array}
\]

This is just a different representation of \(f\), as we see by swapping the rows, so \(f_{\alpha,\beta,\gamma} = f\). But we can’t have \(h_{\alpha,\beta} = h\), because \(\alpha\) is the identity while \(\beta\) is not, so this \(f\) has no \(S(C)\)-equivariant quotient, hence \(S(C)\) is not finitely cancelling.

We can simplify the display of this example as follows:

\[
\begin{array}{c|cc}
  & 1 & 2 \\
\hline
  a & 1 & 2 \\
  b & 2 & 1 \\
\end{array}
\]
We don’t need column labels as these aren’t being permuted; leaving out the labels from \(C\) in the table entries indicates this is a parallel bijection.

The example extends in an obvious way to show that \(S(C)\) is not finitely cancelling if \(|C| > 1\). For example, take \(C = \{a, b, c\}\), and

\[
\begin{array}{ccc}
  a & 1 & 2 & 3 \\
  b & 2 & 3 & 1 \\
  c & 3 & 1 & 2 \\
\end{array}
\]

\((a, b, c)(1, 2, 3)\)

These examples come from the regular representation of a cyclic group. A similar construction works for any finite group \(G\). (Cf. 5 below.) While we don’t need it for what is to follow, we pause to illustrate the construction in the case of the noncyclic group \(C_2 \times C_2\), whose regular representation is the Klein 4-group \(\{(a)(b)(c)(d), (a, b)(c, d), (a, c)(b, d), (a, d)(b, c)\}\):

\[
\begin{array}{cccc}
  a & 1 & 2 & 3 \\
  b & 2 & 1 & 4 \\
  c & 3 & 4 & 1 \\
  d & 4 & 3 & 2 \\
\end{array}
\]

\((a, b)(c, d)(1, 2)(3, 4)\)

\((a, c)(b, d)(1, 3)(2, 4)\)

This bijection is more symmetrical than we need to show this \(\Gamma\) is not cancelling, because \(\Gamma\) has a subgroup the two element subgroup generated by \((a, b)(c, d)\), and to show this is noncancelling we can just duplicate our first example above:

\[
\begin{array}{cc}
  a & 1 \\
  b & 2 \\
  c & 1 \\
  d & 2 \\
\end{array}
\]

\((a, b)(c, d)(1, 2)\)

By now it is clear how to handle any nontrivial permutation all of whose cycles have the same length. Such permutations are called *semiregular*. A permutation group is semiregular just if every non-trivial element is semiregular. (Such groups are also called ‘fixed point free’, but this invites confusion with groups with no globally fixed point.) To sum up:
**Proposition 3** (Feldman-Propp). No permutation group containing a semiregular subgroup is finitely cancelling.

Going further, Feldman and Propp give a beautiful algebraic proof of the following:

**Theorem 4** (Feldman-Propp). A permutation group is finitely cancelling just if it has a globally fixed point.

For further discussion, see 6.1 below. For now, we’re set: We already have the tools to dispose of the infinite case.

### 4 Not fully cancelling

When $A$ and hence $B$ may be infinite, known division methods depend on fixing an ordering for $C$. This raises the suspicion that no nontrivial permutation group can be fully cancelling.

**Theorem 5.** A permutation group is fully cancelling just if it is trivial.

In other words, if we demand complete equivariance for $A$ and $B$, we can’t demand any equivariance at all for $C$.

The proof will proceed via a string of examples.

We begin by slightly varying the construction used above in the finite case, substituting non-parallel bijections.

- $(a, b)$

  $\begin{array}{c|cc}
  a & Ka & Kb \\
  b & Qb & Qa \\
  \end{array}
  
  (a, b)(K, Q)$

- $(a, b, c)$

  $\begin{array}{c|ccc}
  a & Ka & Kb & Kc \\
  b & Qb & Qc & Qa \\
  c & Jc & Ja & Jb \\
  \end{array}
  
  (a, b, c)(K, Q, J)$
• \((a, b)(c, d)\) (not the simplest example; better for generalization)

\[
\begin{array}{ccccc}
a & Ka & Kb & Kc & Kd \\
b & Qb & Qa & Qd & Qc \\
c & Ja & Jb & Jc & Jd \\
d & Xb & Xa & Xd & Xc \\
\end{array}
\]

\((a, b)(c, d)(K, Q)(J, X)\)

Now we jazz up these examples to include fixed points for the action on \(C\), which we can’t do in the finite case.

• \((a, b)(c)\)

\[
\begin{array}{ccccc}
a & Ka & Kb & Kc & 1a & 2a & 3a & \ldots \\
b & Qb & Qa & Qc & 1b & 2b & 3b & \ldots \\
c & 1c & 2c & 3c & 4c & 5c & 6c & \ldots \\
\end{array}
\]

\((a, b)(K, Q)\)

• \((a, b, c)(d)\)

\[
\begin{array}{ccccc}
a & Ka & Kb & Kc & Kd & 1a & 2a & 3a & 4a & \ldots \\
b & Qb & Qc & Qa & Qd & 1b & 2b & 3b & 4b & \ldots \\
c & Ja & Jb & Jc & Jd & 1c & 2c & 3c & 4c & \ldots \\
d & 1d & 2d & 3d & 4d & 5d & 6d & 7d & 8d & \ldots \\
\end{array}
\]

\((a, b, c)(K, Q, J)\)

• \((a, b, c)(d)(e)\)

\[
\begin{array}{ccccc}
a & Ka & Kb & Kc & Kd & Ke & 1a & 2a & 3a & 4a & \ldots \\
b & Qb & Qc & Qa & Qd & Qe & 1b & 2b & 3b & 4b & \ldots \\
c & Ja & Jc & Ja & Jb & Jd & Je & 1c & 2c & 3c & 4c & \ldots \\
d & 1d & 2d & 3d & 4d & 5d & 6d & 7d & 8d & 9d & \ldots \\
e & 1e & 2e & 3e & 4e & 5e & 6e & 7e & 8e & 9e & \ldots \\
\end{array}
\]

\((a, b, c)(K, Q, J)\)
• \((a, b)(c, d)(e)\)

\[
\begin{array}{cccccc}
\mathbf{a} & K_a & K_b & K_c & K_d & K_e \\
\mathbf{b} & Q_b & Q_a & Q_d & Q_e & 1b \\
\mathbf{c} & J_a & J_b & J_c & J_d & J_e \\
\mathbf{d} & X_b & X_a & X_d & X_e & 1d \\
\mathbf{e} & 1e & 2e & 3e & 4e & 5e & 6e & 7e & 8e & 9e & \ldots
\end{array}
\]

These examples illustrate the method to prove that we can never require any kind of equivariance for \(C\). The reason is that any nontrivial \(\Gamma\) will contain some element that is a product of one or more disjoint non-trivial cycles of the same length, together with some fixed points.

5 More about the regular representation

For future reference, let’s look more closely at the construction that we’ve been using, based on the regular representation.

Fix a finite group \(G\). Take \(A = B = C = G\),

\[
f = \{(x, y), (xy, y)\}.
\]

(The unbound variables \(x\) and \(y\) are understood to range over \(G\).) First we observe that any quotient \(h\) that is even \(S_0(C)\)-equivariant will need to agree with one of the ‘rows’ \(f|_c\) of \(f\). To see this, fix \(g \in G\) and set

\[
\alpha = \beta = \{(x, gx)\}.
\]

(The unbound variable \(x\) is understood to range over \(G\); you get the idea.) Now

\[
f_{\alpha, \beta, \text{id}} = \{(gx, y), (gx, y)\} = \{((x', y), (x', y))\} = f,
\]

so

\[
h(g) = h_{\alpha, \beta}(g) = \alpha^{-1} \triangleleft h \triangleleft \beta(g) = gh(g^{-1}g) = gh(1) = f|_{h(1)}(g).
\]

Since this holds for every \(g \in G\),

\[
h = f|_{h(1)}.
\]
Any row of $f$ will do as an $S_0(C)$-equivariant quotient, but we can’t have equivariance for any non-trivial element of $G$ acting on the right. Indeed, for any $g \in G$, we can take
\[
\beta = \gamma = \{(x, xg)\},
\]
\[
f_{\text{id}, \beta, \gamma} = \{((x, yg), (xyg, yg))\} = \{((x, g'), (xg', g'))\} = f.
\]
So we must have
\[
h = h_{\text{id}, \beta} = h \triangleleft \beta,
\]
that is,
\[
h(x) = h(x)g,
\]
but this is impossible if $g$ is not the identity.

6 Unfinished business

6.1 Back to the finite case

Having determined exactly which groups $\Gamma \subset S_C$ are fully cancelling, we naturally turn our attention back to the finite case. We’ve quoted Feldman and Propp’s result (Theorem 4) that $\Gamma$ is finitely cancelling just if it has a globally fixed point. We’ve see that this condition is sufficient, and shown that if $\Gamma$ contains a fixed-point free subgroup it is not finitely cancelling. What about intermediate cases, like the cyclic group generated by $(a, b, c)(d, e)$, i.e. the group generated by $(a, b, c)$ and $(d, e)$, where there is no fixed-point free subgroup? Or the Klein-like 4-group
\[
\{\text{id}, (a, b)(c, d), (a, b)(e, f), (c, d)(e, f)\},
\]
where there are no fixed-point free elements at all? Feldman and Propp’s beautiful algebraic proof does not immediately provide counterexamples, though it gives a method to produce them. They ask [3, Problem 4] for more direct combinatorial arguments.
Let’s at least dispose of \((a,b,c)(d,e)\):  

\[
\begin{array}{cccccccccccc}
\bar{0} & 0 & 0 & 0 & \bar{0} & 0 & 2 & \bar{1} & 0 & 1 & 1 & 1 & 2 & 0 & 0 & 1 & 2 & 10 & 11 & 12 \\
0 & 0 & 0 & 1 & 0 & 2 & 10 & 11 & 12 & 0 & 0 & 0 & 1 & 0 & 2 & 0 & 0 & 0 & 1 & 1 & 1 & 2 & 10 \\
\bar{0} & 0 & 2 & 0 & 0 & \bar{1} & \bar{2} & \bar{1} & 0 & 1 & 1 & 0 & 1 & 0 & 2 & 0 & 0 & 0 & 1 & 1 & 1 & 1 & 2 & 10 \\
0 & 0 & 0 & 1 & 0 & 2 & \bar{1} & \bar{1} & \bar{2} & 10 & 11 & 12 & 0 & 0 & 0 & 1 & 0 & 2 & 10 & 11 & 12 \\
1 & 0 & 1 & 1 & \bar{1} & 12 & 00 & 0 & 1 & 0 & 2 & \bar{1} & \bar{1} & \bar{1} & 2 & 0 & 0 & 1 & 0 & 2 \\
0 & \bar{0} & \bar{0} & 0 & \bar{1} & \bar{2} & \bar{1} & \bar{0} & 0 & 1 & 2 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 1 & 0 & 1 & 1 & 1 & 2 & 10 \\
\end{array}
\]

\((a,b,c)(0,\bar{0},0,\bar{1},\bar{2})(\bar{1}0,\bar{1}1,\bar{1}2)(00,01,02), (10,11,12)\)

\((d,e)(0\bar{0},1\bar{0})(0\bar{1},1\bar{1})(0\bar{2},\bar{1}2)(00,10)(01,11)(02,12)\)

\((a,b,c)(d,e)(0,\bar{0},0,\bar{1},\bar{2})(\bar{1}0,\bar{1}1,\bar{1}2)(0\bar{0},10)(0\bar{1},1\bar{1})(0\bar{2},\bar{1}2)(00,11,02,10,01,12)\)

This arises as follows. Start with bijections

\[p : X_1 \times \{a,b,c\} \to X_2 \times \{a,b,c\}; \quad q : Y_1 \times \{d,e\} \to Y_2 \times \{d,e\},\]

\[
p = \begin{array}{l}
0 & 1 & 2 \\
a & 0 & 1 & 2 \\
b & 1 & 2 & 0 \\
c & 2 & 0 & 1 \\
\end{array}
\]

\((\bar{0},\bar{1},2)(0,1,2)\)

\[
q = \begin{array}{l}
0 & 1 \\
d & 0 & 1 \\
e & 1 & 0 \\
\end{array}
\]

\((\bar{0},\bar{1})(0,1)\)

The inverses

\[p^{-1} : X_2 \times \{a,b,c\} \to X_1 \times \{a,b,c\}; \quad q^{-1} : Y_2 \times \{d,e\} \to Y_1 \times \{d,e\}\]

are

\[
p^{-1} = \begin{array}{l}
0 & 1 & 2 \\
a & 0 & 1 & 2 \\
b & 2 & 0 & 1 \\
c & \bar{1} & 2 & 0 \\
\end{array}, \]

\[
q^{-1} = \begin{array}{l}
0 & 1 \\
d & 0 & 1 \\
e & 1 & 0 \\
\end{array}.
\]

10
Take the disjoint unions \( X = X_1 \cup X_2 \) and \( Y = Y_1 \cup Y_2 \) and augment \( p \) and \( q \) to involutions

\[
P = p \cup p^{-1} \in S(X \times \{a, b, c\}); \quad Q = q \cup q^{-1} \in S(Y \times \{d, e\}).
\]

Take products with the identity and combine to get an involution

\[
F = P \times \text{id}_Y \cup Q \times \text{id}_X \in S(X \times Y \times \{a, b, c, d, e\}).
\]

Let

\[
A = X_1 \times Y_1 \cup X_2 \times Y_2
\]

and

\[
B = X_2 \times Y_1 \cup X_1 \times Y_2.
\]

Separate the involution \( F \) into pieces

\[
F = f \cup f^{-1},
\]

\[
f : A \times \{a, b, c, d, e\} \to B \times \{a, b, c, d, e\}.
\]

This checkered Cartesian product construction can be extended to cover any permutation without fixed points. Any transitive permutation group contains such an element, because the average number of fixed points is 1, and the identity has more. So no transitive permutation group is finitely cancelling.

This construction also takes care of our Klein-like 4-group. In fact, it should handle any subdirect product of nontrivial cyclic permutation groups (cf. Hall [4, p. 63]). Now (asks Shikhin Sethi), what about the 6-element group

\[
\Gamma = \{\text{id}, (a, b, c), (b, c, a), (a, b)(d, e), (a, c)(d, e), (b, c)(d, e)\}?
\]

### 6.2 Deducing an ordering from a division method

A division method for \( C \) associates to any bijection

\[
f : A \times C \to B \times C
\]

a quotient bijection \( Q(f) \) with the property that for any bijections

\[
\alpha : A \to A', \quad \beta : B \to B',
\]

11
for the transformed division problem
\[ f_{\alpha, \beta} = (\alpha^{-1} \times \text{id}_C) \lhd f \lhd (\beta \times \text{id}_C) : A' \times C \to B' \times C \]
the quotient
\[ Q(f_{\alpha, \beta}) : A' \to B' \]
satisfies
\[ Q(f_{\alpha, \beta}) = Q(f)_{\alpha, \beta} = \alpha^{-1} \lhd Q(f) \lhd \beta. \]

A division method produces \( S_0(C) \)-equivariant quotients, as we see by restricting \((\alpha, \beta)\) to \( S(A) \times S(B) \), but more is required. The method must not only respect symmetries of a particular problem, it must give the same answer when presented with the same problem in a different guise. To see the distinction, consider that for an \( f \) with no symmetries, any bijection \( h : A \to B \) is an \( S_0(C) \)-equivariant quotient, and if a division method were required merely to respect the symmetries of \( f \), it could return a bijection depending on stupid properties of the set \( A \), like whether it consists entirely of natural numbers.

Once again we distinguish between full and finite division methods. The method of Feldman and Propp is equivariant, and yields finite division methods (one for each choice of basepoint in \( C \)). In the infinite case we get division methods that depend on fixing an ordering of \( C \), and this dependence on the ordering seems to be unavoidable.

**Problem 1.** Can we equivariantly associate a total ordering of \( C \) to any full division method for \( C \)?

In the finite case, we ask:

**Problem 2.** Can we equivariantly associate a single point in \( C \) to any finite division method for \( C \)?

The equivariance we’re asking for here means that we can’t make arbitrary choices that favor one ordering or point of \( C \) over another. Rather than fuss over the definition, let’s consider the particular case of division by three.

First, a general observation: If \( Q(f) = f|_c \) then \( Q(f_{\alpha, \beta}) = f_{\alpha, \beta}|_c \). Indeed, for any \( f \) we have
\[ (f|_c)_{\alpha, \beta} = f_{\alpha, \beta}|_c, \]
so if \( Q(f) = f|_c \),
\[ Q(f_{\alpha, \beta}) = Q(f)_{\alpha, \beta} = (f|_c)_{\alpha, \beta} = f_{\alpha, \beta}|_c. \]
Now take \( C = \{a, b, c\} \). Consider the six bijections of the form

\[
f[x, y, z] = \begin{bmatrix}
0 & 1 & 2 \\
x & 0 & 1 \\
y & 1 & 2 \\
z & 2 & 0
\end{bmatrix},
\]

\((\bar{0}, \bar{1}, \bar{2})(0, 1, 2)\)

where we propose to plug in for \( x, y, z \) each of the six arrangements of \( a, b, c \). These six problems are really one and the same problem in six different guises, because

\[
f[x, y, z]_{\text{id},(0,1,2)} = \begin{bmatrix}
0 & 1 & 2 \\
x & 1 & 2 \\
y & 2 & 0 \\
z & 0 & 1
\end{bmatrix} = \begin{bmatrix}
0 & 1 & 2 \\
x & 1 & 2 \\
y & 2 & 0 \\
z & 0 & 1
\end{bmatrix} = f[z, x, y],
\]

and

\[
f[x, y, z]_{(1,2),(1,2)} = \begin{bmatrix}
0 & 2 & 1 \\
x & 0 & 2 \\
y & 2 & 0 \\
z & 1 & 0
\end{bmatrix} = \begin{bmatrix}
0 & 2 & 1 \\
x & 0 & 2 \\
y & 2 & 0 \\
z & 1 & 0
\end{bmatrix} = f[z, x, y].
\]

A division method must produce a quotient respecting the symmetry

\[
f[x, y, z]_{(0,1,2),(0,1,2)} = f[x, y, z],
\]

so it must conjugate the cycle \((\bar{0}, \bar{1}, \bar{2})\) to the cycle \((0, 1, 2)\). There are three ways to do this, corresponding to the three rows \( x, y, z \) in the table, so (as
observed in section 5) the quotient bijection $Q(f[x, y, z])$ distinguishes one of the three elements of $C$, which we call $*[x, y, z]$:

$$Q(f[x, y, z]) = f[x, y, z]|_{*[x, y, z]}.$$  

By the general result above, these six basepoints $*[x, y, z]$ all coincide. So we can distinguish a basepoint in $* \in C$ without making any arbitrary choices of how to order the elements of $C$. This is the kind of equivariance we’re looking for.

For a finite division method, that’s as far as we can go. In the infinite case, say that our distinguished basepoint $*$ is $c$. We continue by presenting the two problems $f[a, b], f[b, a]$, where

$$
\begin{array}{c|cccccccc}
  & 1 & 2 & 3 & 4 & 5 & 6 & \ldots \\
  x & Kx & Ky & Kc & 1x & 2x & 3x & \ldots \\
  y & Qy & Qx & Qc & 1y & 2y & 3y & \ldots \\
  c & 1c & 2c & 3c & 4c & 5c & 6c & \ldots \\
\end{array}
$$

The bijection $f[x, y]$ in effect associates $K$ with $x$ and $Q$ with $y$; depending on where $K$ and $Q$ wind up under the quotient bijection $Q(f[x, y])$ (or rather, its inverse), we can pick $K$ over $Q$, hence $x$ over $y$. Our preference of $a$ over $b$ will be the same whether we use $f[a, b]$ or $f[b, a]$, because these are really the same problem:

$$f[x, y]|_{\text{id},(K,Q)} = f[y, x].$$

Now, what about division by four? Or five?

### 6.3 Parallelizing a bijection

We’ve already observed that while $\Gamma$ is finitely cancelling just if every parallel bijection has an equivariant quotient, if $\Gamma$ is not finitely cancelling there could be special bijections $f$ which have a $\Gamma$-equivariant quotient, while their Feldman-Propp parallelizations $\bar{f}$ do not.

**Problem 3.** If a finite bijection $f : A \times C \to B \times C$ has a $\Gamma$-equivariant quotient, must the parallelization $\bar{f}$ also have a $\Gamma$-equivariant quotient?

We haven’t thought very hard about this one.
6.4 Special cases

There are plenty of other questions we could ask, say concerning restrictions that will guarantee that $S(C)$-equivariant division is possible. For example, we might fix $n, k$ and ask whether $S(C)$-equivariant division is always possible when $|A| = |B| = n$ and $|C| = k$. It is easy to see that in this case we must have $\gcd(k, n!) = 1$, i.e. $k$ must have no prime factor $\leq n$. This condition is sufficient for $n = 1, 2, 3$ and maybe 4; the proofs get more involved as $n$ increases. On the other hand, an example (thanks to John Voight) shows that division is not always possible when $n = 8$ and $k = 11$.

Thanks

Thanks to David Feldman and Shikhin Sethi for crucial advice.
